Hadron multiplicities in nucleus–nucleus interactions are calculated in the Dual Parton Model and its dependence on the number of collisions and the number of participants is analyzed. Shadowing corrections are calculated as a function of impact parameter and the multiplicity per participant as a function of centrality is found to be in agreement with experiment at SPS and RHIC energies. The obtained results are used to compute the J/ψ suppression in a comover approach.

1 Charged Multiplicities in the Dual Parton Model

In the Dual Parton Model (DPM) the charged multiplicity per unit rapidity in a symmetric collision is given by¹

$$\begin{aligned} \frac{dN_{AA}^{ch}}{dy}(y, b) = & n_A(b) \left[N_{\mu}^{qq^P - q_v^T}(y) + N_{\mu}^{q_v^P - qq^T}(y) + (2k - 2)N_{\mu}^{q_s - \bar{q}_s} \right] + \\ & \left(n(b) - n_A(b) \right) \left(2k N_{\mu}^{q_s - \bar{q}_s}(y) \right) . \end{aligned} \quad (1)$$

Here P and T stand for the projectile and target nuclei, $n(b)$ is the average number of binary collisions and $n_A(b)$ the average number of participants of nucleus A . These quantities can be computed in a Glauber model. k is the average number of inelastic collisions in pp and $\mu(b) = kn(b)/n_A(b)$ is the total average number of collisions suffered by each nucleon.

In the DPM each inelastic collision leads to two strings and the total number of strings is $2kn$. The charged multiplicity produced by a single string is obtained by a convolution of momentum distribution functions and fragmentation function, and it depends on μ due to energy conservation. We see from (1) that the multiplicity is given by a linear combination of n_A and n with coefficients which depend on the impact parameter b (via $\mu(b)$).

Figure 1: a): The values of $dN^{ch}/d\eta/n_{part}$ versus n_{part} for $PbPb$ collisions at $\sqrt{s} = 17.3$ GeV in the range $-0.5 < \eta_{cm} < 0.5$ computed from eq. (1), compared with the WA98 data³. b): The values of $dN^{ch}/d\eta/(0.5n_{part})$ for $Au-Au$ collisions at $\sqrt{s} = 130$ GeV in the range $-0.35 < \eta_{cm} < 0.35$ computed from eq. (1) taking into account shadowing corrections (see main text). They are compared to the data⁴.

Shadowing corrections in Gribov theory are universal², i.e. they apply both to soft and hard processes. They are closely related to the size of diffractive production and, thus, are controlled by triple Pomeron diagrams. The reduction of the multiplicity resulting from shadowing corrections has been computed in². These corrections are negligible at SPS energies but at RHIC energies they reduce the multiplicity by 40 to 50%.

We present the results¹ obtained at two different energies : $\sqrt{s} = 17.3$ and 130 GeV. The corresponding non-diffractive cross-sections are $\sigma_{ND} = 26$ and 33 mb, respectively. We take $k = 1.4$ and 2.0 corresponding to $dN_{pp}^{ND}/dy = 1.56$ and 2.72. The result in absence of shadowing at $\sqrt{s} = 17.3$ is shown in Fig 1 (a) (solid line). We obtain a mild increase of the multiplicity per participant consistent with the results of the WA98 Collaboration³. This increase gets stronger with increasing energies. As we pointed out before, shadowing corrections are negligible at SPS energies but their effect is large at RHIC. Unfortunately, shadowing corrections have a rather large uncertainty at RHIC energies. Two alternative calculations¹ of shadowing lead to the results at $\sqrt{s} = 130$ GeV shown by the solid lines in Fig 1 (b). Clearly, with the larger values of the shadowing corrections we obtain a quantitative agreement with the PHENIX data⁴.

Note that our calculations refer to dN/dy while the first RHIC measurements refer to $dN/d\eta$. The latter is, of course, smaller at mid rapidities. This difference is negligibly small as SPS where the laboratory pseudo-rapidity variable is used. However, at $\sqrt{s} = 130$ GeV where η_{cm} is used instead, their ratio can be as large as 1.3⁵.

2 J/ψ suppression

Now we are going to use these multiplicities, computed in the framework of DPM, to determine the J/ψ suppression in the comovers approach. In this model, the J/ψ survival probability is the product of two factors $S_{abs}(b, s) \cdot S_{co}(b, s)$. The first factor represents the suppression due to nuclear absorption of the $c\bar{c}$ pair. Its expression, given by the probabilistic Glauber model, is well known. It contains a parameter, the absorptive cross-section σ_{abs} . The second factor $S_{co}(b, s)$ represents the suppression resulting from the interaction with comovers. Its expression^{6,7} depends on the averaged interaction cross-section σ_{co} and on the value of the multiplicity at

each b in the region of the dimuon trigger ($0 < y^* < 1$), for which we take the results of section 1, ($N_{y_{DT}}^{co}$ is the charged multiplicity; the factor $3/2$ takes care of the neutrals)

$$S_{co}(b, s) = \exp \left\{ -\sigma_{co} \frac{3}{2} N_{y_{DT}}^{co}(b, s) \ln \left[\frac{\frac{3}{2} N_{y_{DT}}^{co}(b, s)}{N_f} \right] \right\} . \quad (2)$$

Experimentally, the ratio of J/ψ over DY is plotted as a function of either E_T or the energy of the zero degree calorimeter E_{ZDC} . E_T is the transverse energy of neutrals deposited in the NA50 calorimeter, located in the backward hemisphere ($1.1 < y_{lab} < 2.3$). Using the proportionality between E_T and multiplicity, we have

$$E_T(b) = \frac{1}{2} q N_{y_{cal}}^{co}(b) . \quad (3)$$

Here the multiplicity of comovers is determined in the rapidity region of the NA50 calorimeter. The energy of the zero degree calorimeter is defined as

$$E_{ZDC}(b) = [A - n_A(b)]E_{in} + \alpha n_A(b)E_{in} , \quad (4)$$

Here n_A is the number of participants, $A - n_A$ the number of spectators, and $E_{in} = 158$ GeV is the beam energy. The last term represents the small fraction of wounded nucleons and/or fast secondaries that hit the ZD Calorimeter. The values of q and α are obtained, respectively, from a fit of the tails of the E_T and E_{ZDC} distributions. With the obtained values, the measured $E_T - E_{ZDC}$ correlation is well reproduced.

We see from Eqs. (2) and (3) that, in order to describe the centrality dependence of the J/ψ suppression, it is paramount to have a good description of the b dependence of N_y^{co} – both in the rapidity region of the dimuon trigger and in the one of the E_T calorimeter. In the latter we obtain an scaling in the number of participants, i.e. we recover the wounded nucleon model.

The model allows to compute the ratio J/ψ over DY versus either E_T or E_{ZDC} from peripheral collisions up to the knee of the E_T or E_{ZDC} distributions. To go beyond it, we have to introduce^{7,8} the fluctuations responsible for the tail of the E_T and E_{ZDC} distributions (Eqs. (3) and (4) give only the average values at each b). They have been introduced^{7,8} in the model by multiplying $N_{y_{DT}}^{co}(b)$ in Eq. (2) by $F(b) = E_T/E_T(b)$, where E_T is the measured value of the transverse energy. Likewise, for the suppression versus E_{ZDC} we multiply $N_{y_{DT}}^{co}(b)$ by $n_A(E_{ZDC})/n_A(b)$ where $n_A(E_{ZDC})$ is obtained from Eq. (4): $n_A(E_{ZDC}) = (AE_{in} - E_{ZDC})/E_{in}(1 - \alpha)$.

The results are presented in Fig. 2 and compared with the NA50 data⁹. We see that from peripheral collisions up to the knee of the E_T distribution, the data are well described. However, beyond the inflexion point at the knee, the decrease in the data is sharper than in the model. Note, however, that the data beyond the knee are obtained with the so-called minimum bias (MB) analysis. Only the ratio J/ψ over MB is measured and it is multiplied by a theoretical ratio DY/MB. In the model used by NA50, this ratio is essentially flat beyond the knee – due to the fact that the tail of the E_T distribution of hard (DY) and soft (MB) processes is assumed to be the same. The behaviour of the MB NA50 data beyond the knee can be explained¹⁰ by the combined effects of a small decrease of the hadronic E_T in the J/ψ event sample (due to the E_T taken by the J/ψ trigger), together with the sharp decrease of the E_T distributions in this tail region. This phenomenon does not affect the (true) ratio J/ψ over DY (obtained in the NA50 standard analysis), but does affect the one obtained by the so-called minimum bias analysis¹⁰.

The results¹¹ of the model as a function of E_{ZDC} are presented in Fig. 2 (b). The centrality dependence of the J/ψ suppression is reasonably well reproduced except for the broad bump centered at $E_{ZDC} \sim 12$ TeV. No such structure is seen in the E_T distribution at the same b ($E_T \sim 85$ GeV). Note that the suppression beyond the knee ($E_{ZDC} \lesssim 5$ TeV) is well reproduced by the model. This was to be expected since the tail of the E_{ZDC} distribution is not affected by

Figure 2: a): Ratio J/ψ over DY versus E_T compared to NA50 data⁹. The full curve is the theoretical prediction with E_T fluctuations and the dashed line contains E_T fluctuations and the E_T loss induced by the J/ψ trigger¹⁰. b): Ratio J/ψ over DY versus E_{ZDC} compared to preliminary results presented by NA50⁹. The full line is obtained¹¹ computing for each b , the value of E_{ZDC} and the value of the ratio R , taking into account fluctuations and changing the normalization by a factor 0.94. In both figures the dotted line is the NA50 absorption model, fitting pA and SU. The used parameters are $\sigma_{abs} = 4.5$ mb, $\sigma_{co} = 1$ mb, $q = 0.62$, $\alpha = 0.076$ and $N_f = 1.15$ fm⁻².

the presence of the J/ψ trigger. This provides a consistency check of our interpretation of the suppression versus E_T beyond the knee. Note also that the data of Fig. 2 (b) for $E_{ZDC} < 28$ TeV exhibit a J/ψ suppression significantly steeper than the one in the NA50 absorption model – indicating that the anomalous suppression is already present in very peripheral collisions. This confirms the trend already observed in the suppression versus E_T .
